ABSTRACT

Previous studies suggest that extratropical atmospheric variability influences the tropics via the seasonal footprinting mechanism (SFM), in which fluctuations in the North Pacific Oscillation (NPO) impact the ocean via surface heat fluxes during winter and the resulting springtime subtropical SST anomalies alter the atmosphere–ocean system over the tropics in the following summer, fall, and winter. Here, the authors test the SFM hypothesis by imposing NPO-related surface heat flux forcing in an atmospheric GCM coupled to a reduced gravity ocean model in the tropics and a slab ocean in the extratropics. The forcing is only imposed through the first winter, and then the model is free to evolve through the following winter.

The evolution of the coupled model response to the forcing is consistent with the SFM hypothesis: the NPO-driven surface fluxes cause positive SST anomalies to form in the central and eastern subtropics during winter; these anomalies propagate toward the equator along with westerly wind anomalies during spring, reach the equator in summer, and then amplify, which leads to an ENSO event in the following winter. The anomalies reach the equator through a combination of thermodynamically coupled air–sea interactions, namely, the wind–evaporation–SST (WES) feedback and equatorial ocean dynamics. The initial off-equatorial anomaly propagates toward the equator through a relaxation of the climatological easterly winds south of the dominant SST anomalies, which leads to a reduction in upward latent heat flux. These westerly anomalies reach the equator during boreal summer, where they can excite downwelling equatorial Kelvin waves. The connection between off-equatorial variations and tropical ENSO-like conditions may also occur via the excitation of westward-propagating equatorial Rossby waves during spring, which reflect off of the western boundary as Kelvin waves, depressing the thermocline in the eastern Pacific during the following summer. NPO-related anomalies that form during the first winter in the tropical Pacific may also contribute to the development of an El Niño event in the following winter.

The imposition of the NPO-related forcing caused warming in the ENSO region in ~70% of the ensemble of 60 simulations; therefore, the response depends on the state of the tropical atmosphere–ocean system. For years where the control simulation was poised to develop into a neutral or negative ENSO event, the addition of the NPO heat fluxes tended to cause anomalous warming in the tropical Pacific in the following fall/winter; if the control was heading toward a warm ENSO event, the imposition of NPO forcing tends to reduce the amplitude of that event.

1. Introduction

Over the past 25 years two broad paradigms involving nonlinear/unstable or linear/stable atmosphere–ocean interactions have emerged to explain the dynamics underlying El Niño–Southern Oscillation (ENSO). In the pioneering studies using linearly unstable models (Zebiak and Cane 1987; Battisti 1988; Schopf and Suarez 1988), ENSO variability is self-sustained and maintained by nonlinear interactions within the tropical Pacific. Irregular oscillations, as observed in nature, can be introduced by low-order chaos (e.g., Münnich et al. 1991; Jin et al. 1994) resulting from stronger coupling between components of the system or by stochastic forcing (noise) that interrupts regular cycles (Blanke et al. 1997). More recent studies suggest that ENSO is linearly stable (Penland and Sardeshmukh 1995; Chang et al. 1996; Moore and Kleeman 1999; Thompson and Battisti 2000, 2001), where stochastic (external) forcing is essential for maintaining ENSO variability. Several sources of stochastic forcing have been proposed including westerly wind bursts (WWBs) in the central–western equatorial Pacific (e.g., Wyrski 1975; Vecchi and Harrison 2000; McPhaden 2004; Seiki and Takayabu 2007), the Madden–Julian oscillation (e.g., Lau and Chan 1986, 1988; Moore and Kleeman 1999; Zavala-Garay et al. 2008), and variability originating in midlatitudes that subsequently influences westerly wind bursts (Yu and Rienecker 1998; Nakamura et al. 2006, 2007).

Variability initiated in the North Pacific has the potential to influence the tropical Pacific on interannual to decadal time scales via both the ocean and the atmosphere. In the ocean, the extratropics can impact the tropics via the subtropical cell, a shallow meridional overturning circulation. Fluctuations in the temperature and salinity created by air–sea interaction in midlatitudes can be advected to the tropics within the thermocline (the lower layer of the subtropical cell) and then upwell to the surface when they reach the equator (e.g., Gu and Philander 1997). Changes in extratropical winds can also alter the overall strength of the subtropical cell, altering the volume of cold water reaching the equator (Kleeman et al. 1999; McPhaden and Zhang 2002). Alternatively, upper-ocean anomalies can be carried from higher latitudes to the tropics by westward-propagating Rossby waves, which transfer their energy to equatorward-propagating Kelvin waves at the western boundary (Lysne et al. 1997). In the atmosphere, the response to slowly varying SST anomalies in the Kuroshio Extension region can extend into the tropics, thereby affecting the trade winds and decadal variability (Barnett et al. 1999; Pierce et al. 2000).

Midlatitude-to-tropics atmospheric connections may evolve over several seasons and involve additional portions

of the climate system. Based on diagnostics of an extended Commonwealth Scientific and Industrial Research Organisation (CSIRO) coupled general circulation model (CGCM) simulation, Vimont et al. (2001, 2003a) identified the seasonal footprinting mechanism (SFM) where air–sea interaction in the subtropics during the warm season links extratropical atmospheric variability in one winter with tropical variability in the following winter (Fig. 1). Specifically, fluctuations in the North Pacific Oscillation (NPO; Walker and Bliss 1932; Rogers 1981; Linkin and Nigam 2008), the second leading internal atmospheric mode over the North Pacific in winter, impart a sea surface temperature (SST) “footprint” onto the ocean via changes in the surface heat fluxes. The NPO consists of a meridional dipole in sea level pressure (SLP) over the central Pacific, with centers at approximately 35° and 60°N; when low pressure occupies the southern lobe of the NPO, the anomalous winds are from the west opposing the trade winds over the central and eastern subtropical Pacific, reducing the wind speed and upward latent flux, thereby warming the underlying ocean. The reverse set of processes occurs during the opposite phase of the NPO. The SST footprint, which maximizes in late winter/early spring, persists through summer in the subtropics. The atmosphere responds to these SSTs and further interacts with the tropical ocean. The resulting atmospheric circulation includes zonal wind stress anomalies that extend onto the equator in the central and western Pacific. The stress anomalies excite a response in the equatorial ocean that influences the SST and thermocline depth in the central and eastern equatorial Pacific in the subsequent winter. Vimont et al. (2001, 2003a) concluded that the SFM was an important source of external forcing for interannual ENSO variability and decadal to interdecadal tropical variability in the CSIRO CGCM. SLP and SST precursors that resembled those associated with the NPO in the winter prior to ENSO’s peak were also found in the National Center for Atmospheric Research (NCAR) Community Climate System Model, version 2 (CCSM2; Anderson and Maloney 2006).

The SFM appears to occur in nature as well. Vimont et al. (2003b) and Anderson (2003, 2004) found statistically significant links between the NPO (and the western Pacific pattern, its signature in the upper troposphere; Hsu and Wallace 1985) in winter, SSTs in the subtropical North Pacific, and winds in the western tropical Pacific during spring and summer, and SSTs in the ENSO region in the subsequent winter. Several studies have used linear inverse models (LIMs) derived from simultaneous and lagged covariance statistics of observed SST anomalies to better understand and predict ENSO (e.g., Penland and Magorian 1993; Penland and Sardeshmukh

CCM3-RGO CNTRL NDJFM SLP EOF2 16.7% (20N-90N, 110E-70W)

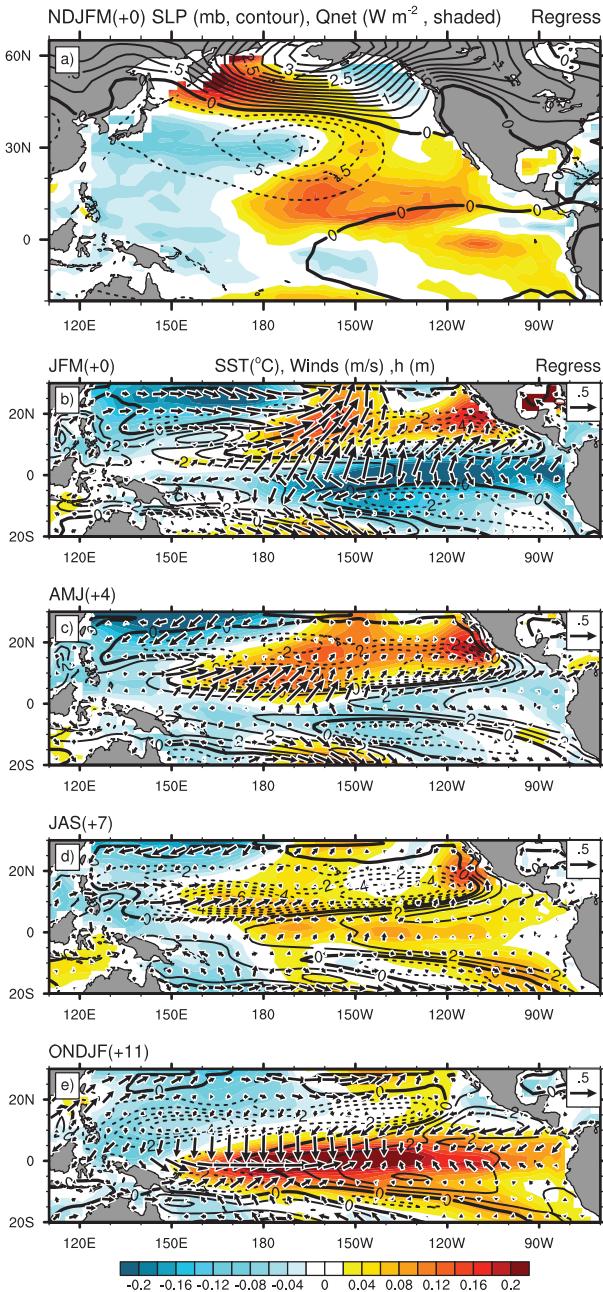

FIG. 1. The SFM simulated in a 100-yr integration of the CCM3-RGO-ML model as indicated by (a) the concurrent regression of SLP [contour interval (CI) is 0.25 mb per std dev] and Q_{net} [color shading interval (CSI) is $1 W m^{-2}$ per std dev, positive into ocean] on the NPO time series [the second PC of SLP for EOFs computed over the North Pacific (20° – 90° N, 110° E– 70° W) during November–March] and lagged regressions of SST (shaded), thermocline depth (CI is 1 m), and wind (vectors) in the tropical Pacific on the NPO time series for (b) JFM, (c) AMJ, (d) JAS, and (e) ONDJF. The SST and wind scales are located at the bottom of the figure and the top-right corner of (b)–(e), respectively.

1995); the springtime SFM SST pattern closely resembles the “optimal structure,” the pattern identified in LIMs as the most likely to grow into a large ENSO event (Penland and Sardeshmukh 1995; Xue et al. 1997; Thompson and Battisti 2001; Alexander et al. 2008). In addition, there is a close correspondence between the development of SST anomalies predicted by LIM and the evolution of the atmosphere–ocean system indicated by the SFM prior to ENSO events (Alexander et al. 2008).

The SFM also influences the latitude of the tropical meridional SST gradient and the intertropical convergence zone (ITCZ): the ITCZ is displaced toward (away from) the hemisphere with anomalously warm (cold) water in the subtropics, and the associated winds flow across the anomalous SST gradient from the negative toward and over the positive SSTA. The variations in the meridional SST gradient and the ITCZ, termed the meridional mode (MM) by Chiang and Vimont (2004), has been well documented in the Atlantic over the past 30 years (e.g., Hastenrath and Heller 1977; Xie and Carton 2004) but was only recently uncovered in the Pacific after accounting for the dominant ENSO signal. In the Pacific, the MM exhibits SST anomalies of one sign extending southwestward from Baja California to the central–western equatorial Pacific with anomalies of the opposite sign in the eastern equatorial Pacific. Chang et al. (2007) and Zhang et al. (2009a,b) present both observational and modeling evidence that the MM is a thermodynamic coupled mode independent of ENSO and that the MM plays an important role in initiating ENSO events.

Although the seasonal footprinting mechanism has been diagnosed in models and observations, several questions remain regarding the scope of the processes involved and its overall relationship to ENSO. For example, because ENSO influences the atmosphere–ocean system over the North Pacific for an extended period of time (e.g., Trenberth et al. 1998; Alexander et al. 2002), is the SFM truly an independent means of forcing ENSO or is it at least partly a component of the ENSO cycle? By what means do the ocean anomalies persist and propagate during the warm season? Do they feed back on the atmospheric circulation in the tropical Pacific? If the SFM does initiate ENSO events, does its efficacy depend on the state of the tropical Pacific? Finally, what is the overall relationship between the SFM, MM, and ENSO?

To examine these questions, Vimont et al. (2009; hereafter VAF) conducted atmospheric GCM (AGCM)–slab ocean model simulations to investigate the tropical Pacific response to midlatitude atmospheric variability. Heat flux anomalies associated with the NPO during boreal winter were used to force the ocean in an ensemble of model simulations, after which the forcing was terminated

and the coupled model was free to evolve. The SST and wind anomalies continued to amplify in the tropical Pacific after the imposed forcing was shut off because of feedbacks between the surface wind, evaporation, and SST (WES feedback) and because of changes in the shortwave radiative heat flux. In the Northern Hemisphere, the response to warm subtropical SSTs includes southwesterlies over and to the southwest of the SST maxima, which slows the trade winds and reduces the upward latent heat flux, warming the ocean and hence leading to positive WES feedback. This thermodynamic coupling results in southwestward development of SST anomalies and an associated equatorward shift in the surface zonal wind anomalies, consistent with previous studies of WES feedback (Xie and Philander 1994; Liu and Xie 1994; Xie 1996) and with studies that examined the tropical air–sea interaction in response to extratropical variability (Xie 1999; Wu and Li 2007).

In this study, we impose the same NPO surface heat flux forcing as used by VAF, but in a coupled model where the ocean contains the dynamics necessary to simulate ENSO. The model, described in section 2, consists of an AGCM that is anomaly coupled to a reduced gravity ocean (RGO) model in the tropics and a slab elsewhere over the ocean. The experiment (Exp) design includes a long control integration and 60 branch simulations from the control, which include additional NPO-related heat flux forcing (section 2). The results, obtained from the difference between the control and branch integrations, are presented in section 3 and summarized and discussed in section 4.

2. Model and experiment design

a. Coupled model

The coupled model, which is described in detail by Zhang et al. (2009a), consists of the NCAR CCM3 coupled to an extended 1.5-layer RGO model in the tropics and a slab mixed layer (ML) model in the extratropics. CCM3, which is described by Kiehl et al. (1998), is a spectral AGCM that employs T42 truncation ($\sim 2.8^\circ$ latitude $\times \sim 2.8^\circ$ longitude) with 18 vertical levels. The model includes parameterizations for radiation, convection, boundary layer, and the diagnostic treatment of clouds; the land surface characteristics and sea ice extent are specified to follow the observed mean seasonal cycle.

The RGO model has been used extensively to study ENSO (e.g., Zebiak and Cane 1987; Battisti 1988). The formulation and parameters used here are from Chang (1994). The model consists of an upper layer, which includes a fixed depth surface mixed layer, overlaying a deep motionless layer. The thermocline is located at base of the upper layer (depth h) and the surface currents

consist of a surface Ekman component and a geostrophic component related to the gradient h . The surface layer temperature (equivalent to the SST) depends on advection by surface currents, upwelling, and heat fluxes with the atmosphere but does not influence the ocean dynamics. The upwelling is based on the divergence of the surface currents. The model resolution is 1° latitude by 2° longitude and its domain extends from 30°N to 30°S in all ocean basins. The extratropical ML depth, which varies spatially but not temporally, is obtained from the annual average mixed layer depth estimated by Monterey and Levitus (1997). There is no smoothing of the SST anomalies across the RGO–ML boundary.

The RGO and ML are anomaly coupled to the CCM3: wind stress anomalies about the AGCM climatology are passed to the RGO model, the surface heat flux anomalies are passed to both the RGO and ML models, and the RGO–ML models transfer the SST anomalies back to the atmosphere. Observed climatological values are added to the anomalies to make the full fields prior to exchanging them between models. The monthly SST and surface flux climatologies are obtained from Reynolds and Smith (1994) and the European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis (Uppala et al. 2005), respectively. A seasonally varying flux correction is also applied to the ocean to keep the SST close to its observed state.

The CCM3–RGO model simulates many aspects of both the MM and ENSO reasonably well, including their temporal and spatial structures as well as their phase locking to the seasonal cycle (Chang et al. 2007; Zhang et al. 2009a). However, it underestimates the amplitude of ENSO variability by about 20% and its period by about 6 months.

Here, we examine a 100-yr control (Cntrl) CCM–RGO–ML simulation to determine the extent to which the SFM occurs in the model. First, the wintertime NPO is defined in the model as the second empirical orthogonal function (EOF) of North Pacific (20° – 90°N , 110°E – 70°W) SLP during November–March (NDJFM). The simulated NPO, shown by the concurrent regression of SLP values on the NPO time series [the second principal component (PC) of SLP in NDJFM], strongly resembles its counterpart in nature with a meridional dipole structure over the central North Pacific (cf. Rogers 1981; Vimont et al. 2003b; Linkin and Nigam 2008). Concurrent regressions of the net surface heat flux Q_{net} and lagged regression of SST and surface winds, also shown in Fig. 1, follow the SFM paradigm: strong fluxes in the subtropical eastern Pacific associated with the southern lobe of the NPO (Fig. 1a); the formation of SST and wind anomalies that develop in winter and into spring in the subtropics (Figs. 1b,c); wind anomalies that extend southwestward

toward the equator in summer (Fig. 1d); and the development of an ENSO event in the subsequent fall/winter (Fig. 1e). The SST values in Fig. 1b resemble the MM with anomalies of opposite sign on the equator and from 10° to 20°N in the eastern half of the basin. The h values, also shown in Fig. 1, are suggestive of a La Niña-like state during the first winter, with negative (shallower) anomalies in the east and positive anomalies in the west that evolve toward a El Niño-like state by the following winter with a deeper thermocline in the central equatorial Pacific.

b. Model experiments

Although the statistical analysis identifies the SFM in the CCM-RGL-ML simulation, there remains ambiguity surrounding its underlying cause (e.g., the NPO signal may be a response to some feature of the ENSO cycle). Thus, we test the SFM hypothesis by conducting experiments in which an external forcing is added to the ocean components of the CCM-RGO-ML model. The imposed forcing represents the net surface heat flux Q_{net} anomalies associated with the NPO during boreal winter. In nature and/or coupled models, the NPO-related fluxes contain forcing associated with internal atmospheric variability; feedback from the ocean; and NPO-related variability driven by anomalies in other parts of the climate system, which could include ENSO. To cleanly separate the part of the NPO forcing that is due to intrinsic atmospheric variations, the NPO-related heat fluxes were extracted from a 200-yr NCAR Community Atmospheric Model, version 3 (CAM3) simulation with repeating climatological SSTs as boundary conditions. A different analysis technique applied to observations yields a very similar structure and amplitude of NPO-related heat flux variations (see VAF for a comparison between the two methods).

The NPO-related heat fluxes are obtained through application of EOF analysis to the winter (NDJFM) averaged SLP anomalies from the uncoupled CAM3 simulation over the North Pacific domain. As in the CCM3-RGO-ML model, the NPO is identified by the second EOF, which explains 19% of the variance and is well separated from the first EOF (the Aleutian low) and higher-order EOFs. The NPO-related SLP/ Q_{net} fields from CAM3, obtained by regressing the SLP and Q_{net} anomalies onto the second PC, are similar to those in nature as well as in the CCM3-RGO-ML model (cf. Fig. 1 in VAF with our Fig. 1a). Because the NPO is similar in the two models and VAF isolated the intrinsic NPO variability, we use the Q_{net} forcing obtained from CAM3 in this study. The imposed heat flux forcing used here (Fig. 2) is derived by doubling the Q_{net} values regressed onto the second SLP PC (twice those shown in

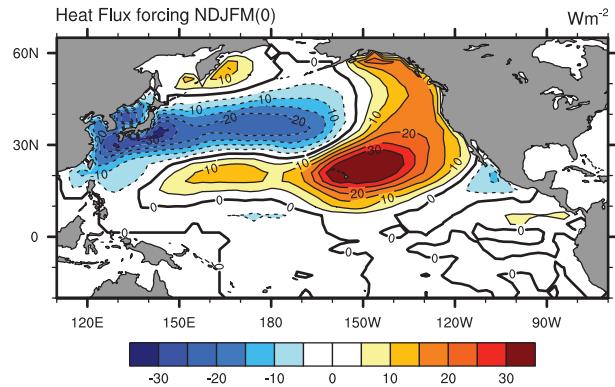

FIG. 2. The NPO-related heat flux forcing added in each of the 60 branch experiments derived from the second EOF of SLP over the North Pacific in an extended AGCM simulation with repeating climatological SSTs. The forcing is obtained by doubling the Q_{net} values (CSI is 5 W m^{-2}) from 20°S to 65°N and from 110°E and 70°W in the Pacific regressed onto the second PC of SLP during NDJFM, which corresponds to a 2σ NPO anomaly in its negative phase (see Fig. 1a).

Fig. 1b of VAF). In these idealized experiments, we have utilized strong forcing (a 2σ anomaly from the mean) to emphasize the footprinting mechanism relative to the background noise. The forcing is in accordance with the negative phase of the NPO, with low pressure south of 45°N (as in Fig. 1a), which is consistent with Linkin and Nigam (2008) and the nomenclature used to describe the North Atlantic Oscillation (NAO).

The experiment consists of 60 branch simulations from the Cntrl, each initialized with conditions on 1 November from the first 60 years of the 100-yr integration. As a result of linearly interpolating monthly input values to the model time step, the amplitude of the heat flux forcing increases from half strength on 1 November to full strength by mid-November and decreases from full strength in mid-March to zero by mid-April. The model simulations continue with unperturbed fluxes through the following April (18 months total). The imposed forcing is identical in each of the branch runs and is added to the Pacific from 20°S to 60°N. An additional set of 10 simulations was conducted where the heat flux forcing was applied from 10° to 60°N (100% north of 9.7°N, 50% at 9.7°N, and 0% south of 9.7°N). The results are presented as the differences between the Exp simulations from the corresponding periods in the Cntrl.

The experiment design will still include some redundancy between the imposed forcing and internally generated NPO variability. Ensemble averaging across the relatively large number of simulations will emphasize the forced model response; VAF found that the experimental design was appropriate for addressing the NPO's influence on tropical climate variability. Differences in

the evolution of individual ensemble members, however, may indicate what aspects of the background variability, including the amplitude of the NPO and the state of the tropical Pacific ocean, are important for the development of ENSO events.

3. Results

a. NPO-forced climate anomalies

The evolution of the model in response to the imposed NPO forcing is depicted in Fig. 3, which shows the ensemble averaged Exp – Cntrl (Δ) for SST, surface winds, and latent heat flux Q_{lh} (which is positive into the ocean and does not include the imposed forcing) during year 0 for January–March [JFM(0)], April–June [AMJ(0)], and July–September [JAS(0)] and during year 1 for October–December [OND(1)]. Regions where the ensemble average of the 60 Exp simulations are significantly different from the control at the 95% level as indicated by the Student's t test are stippled. The SST difference (or anomalies) during JFM(0) reflects the direct response to the oceanic heat flux forcing (cf. Fig. 2 with Fig. 3, top left), which includes warm water that extends both northeastward and westward from Hawaii ($\sim 20^\circ\text{N}$, 150°W) and cold water to the south of Baja California and in the western North Pacific. The atmospheric flow is generally toward the warm water, and the heat fluxes tend to damp the SST anomalies as the anomalously warm (cold) water loses more (less) heat to the atmosphere. A dynamic ocean response begins to develop by JFM(0), with negative thermocline depth h anomalies between approximately 7° and 20°N in the western Pacific and modest positive h anomalies in the central and eastern equatorial Pacific, with a maximum at $\sim 4^\circ\text{N}$ (Fig. 4a). Most of these thermocline depth changes appear to be driven by the local Ekman pumping with a deeper thermocline ($\Delta h > 0$) associated with downward Ekman pumping ($\Delta w_{ek} < 0$) and vice versa (Fig. 4). Given these changes in the atmosphere and ocean, it is apparent that ΔSST also includes anomalies generated by air–sea interaction in addition to those directly resulting from the imposed forcing.

The response continues to evolve once the forcing has ended by mid-April: during AMJ(0), the initial NPO-driven SST signal over the northeastern Pacific decreases but warm water extends farther into the tropics in the central Pacific, with small positive anomalies extending onto and south of the equator in the vicinity of 165°W [consistent with the downward Q_{lh} anomalies during JFM(0) and AMJ(0)]. A cyclonic atmospheric circulation is centered at approximately 18°N , 170°W , with strong southwesterlies in the tropical western Pacific (0° – 15°N , 140°E – 170°W) and northeasterlies extending

across much of the Pacific from 20° to 30°N . In response to the winds, the thermocline deepens from 2° to 7°N across the western half of the Pacific, whereas the positive anomalies on the equator at $\sim 165^\circ\text{W}$ and the negative anomalies farther north have also increased in amplitude (Fig. 4b).

The southwesterly flow in the subtropics opposes the mean trades, reducing the wind speed U and thus the evaporation; indeed, ΔQ_{lh} exceeds 10 W m^{-2} near 10°N between 160°E and 170°W , despite positive ΔSST in the region. Decomposing the wind speed and specific humidity q difference across the sea surface into their mean, obtained from the control, and departure from the control (Δ) indicated that the wind speed fluctuations are primarily responsible for ΔQ_{lh} within $\sim 25^\circ$ of the equator (not shown). The ΔQ_{lh} variability associated with the q fluctuations were of weaker amplitude and generally damp the ΔSST , except in the eastern equatorial Pacific. These interactions between SST, winds, and Q_{lh} are consistent with WES feedback, which is maximized in the tropical western Pacific during boreal spring because of the seasonal cycle in background winds and the strength of the atmospheric response to SSTs (VAF). WES feedback was also identified as a key driver of SST variability in the central and western tropical Pacific of the CCM3 by Mahajan et al. (2009a), although humidity fluctuations were also found to be important, for example, by causing SST anomalies to extend from the extratropics to the subtropics (Mahajan et al. 2009b, manuscript submitted to *J. Climate*).

The difference in precipitation P between the Exp and Cntrl attains maximum amplitude during AMJ(0), when the precipitation increases (decreases) in the central tropical (western equatorial) Pacific (Fig. 5). These dipole precipitation anomalies are similar to those associated with the MM but located farther north and west (cf. Chiang and Vimont 2004). Positive ΔP coincides with the convergence of the surface wind (Fig. 3). The shortwave fluxes at the surface (not shown) are collocated but of opposite sign to ΔP (i.e., less precipitation, lower cloud amount, and more sunlight reaching the surface and vice versa) and thus warm the ocean during AMJ(0) between about 5°S and 10°N in the western Pacific. Although the structure of the latent heat and shortwave fluxes differ, both act to warm the ocean in the vicinity of 5°N , 170°E . The cooperating influence of shortwave and latent heat fluxes is consistent with results from Chiang and Vimont (2004) as well as VAF.

The SST anomalies initially driven by the imposed NPO forcing continue to decrease in the subtropics and northeastern Pacific through JAS. However, air–sea interaction amplifies the anomalous westerly wind, SST, and h on the equator, which are maximized in the

Qflux-CNTRL parallel years

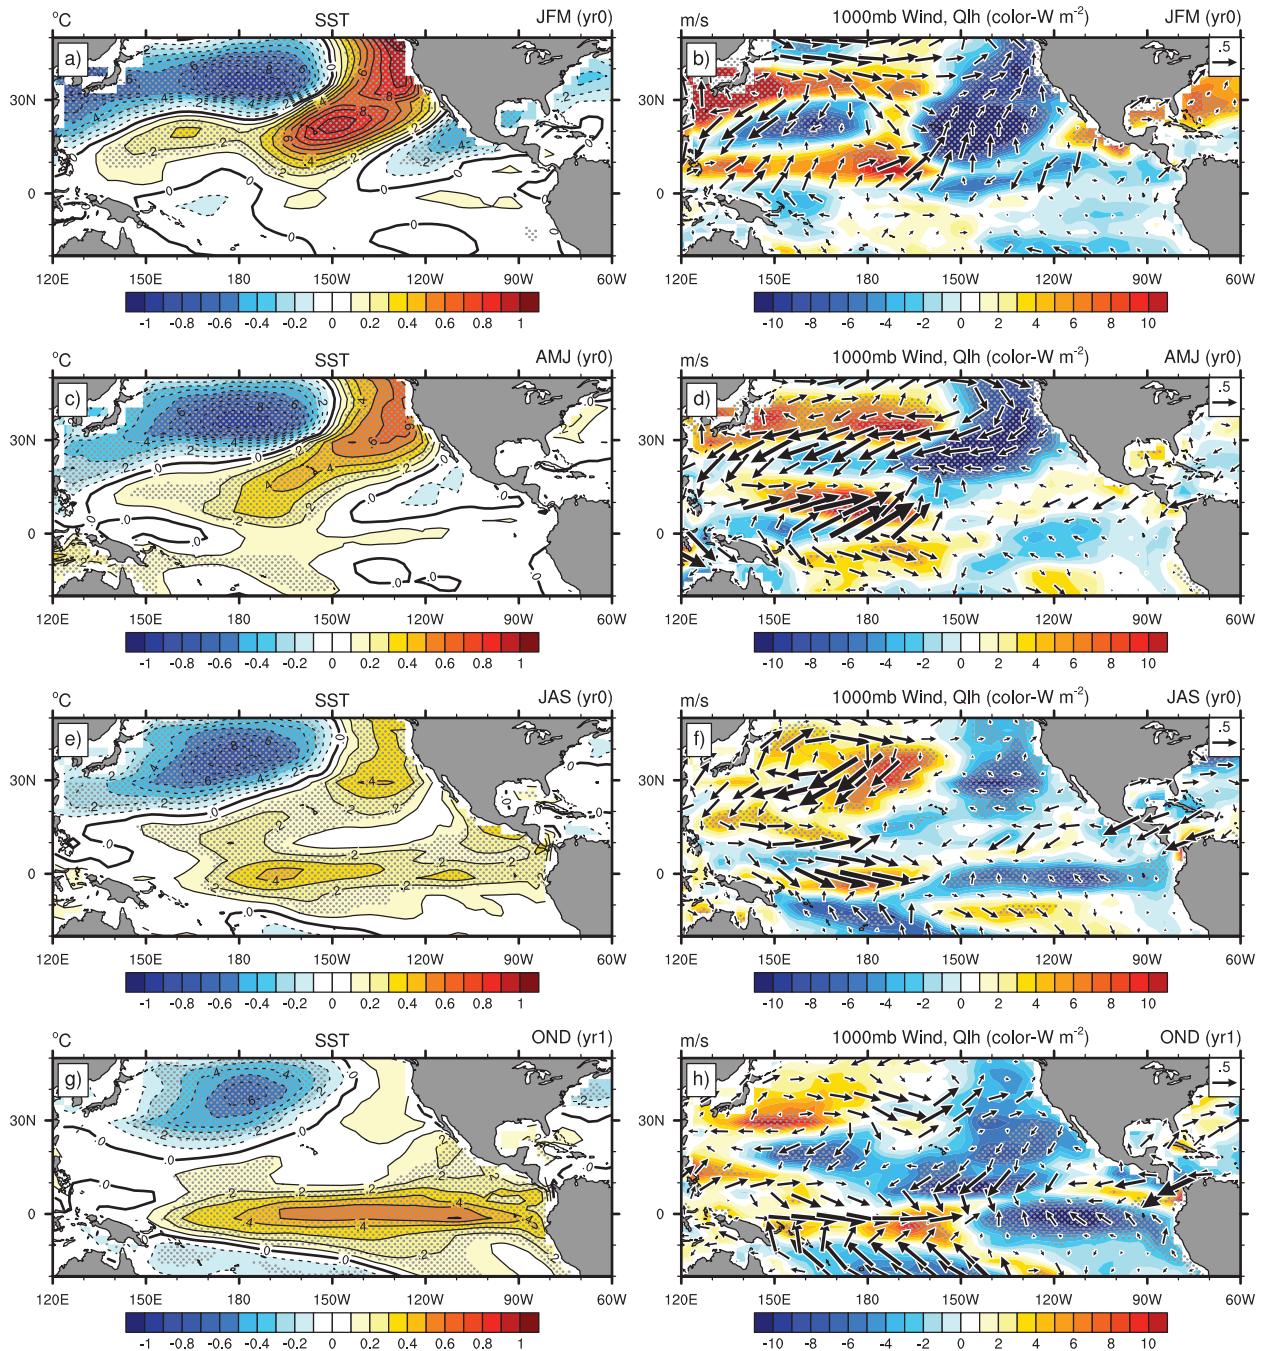

FIG. 3. Evolution of the response to the negative phase of the NPO-related forcing. The ensemble mean difference (Δ) between the “ Q flux” Exp and Cntrl simulations for (left) SST (CI is 0.1°C) and (right) 1000-mb wind (vectors, m s^{-1}) and Q_{lh} (W m^{-2}). The response is shown for (top)–(bottom) JFM(0), AMJ(0), JAS(0), and OND(1), where 0 denotes the initial year of the integration and 1 denotes the following year. Stippling denotes grid squares where t tests indicate that the SST and Q_{lh} from the 60 Exp simulations are significantly different from the control at the 95% level.

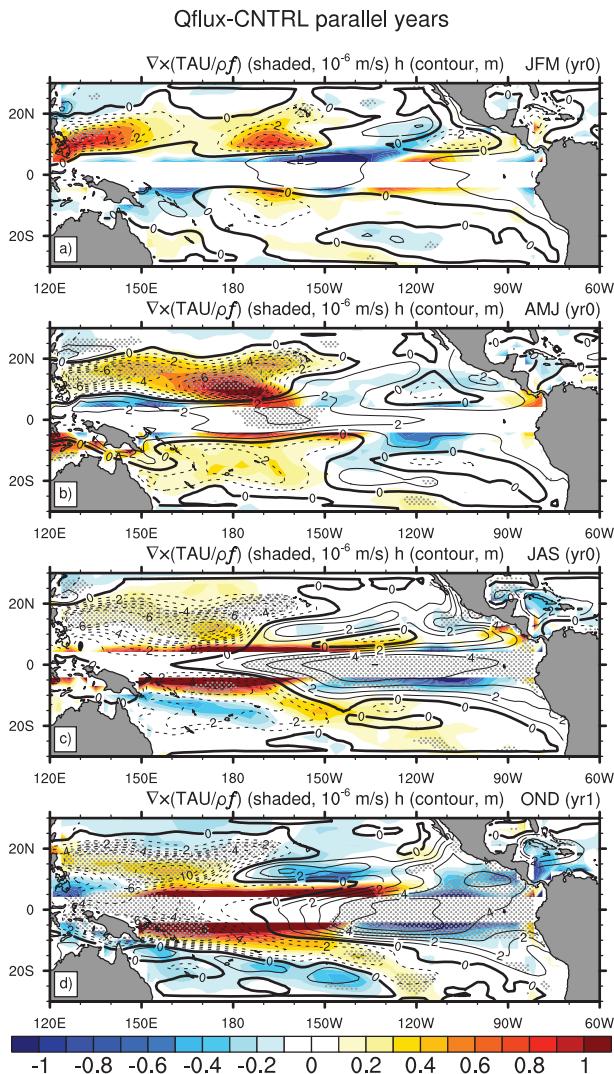

FIG. 4. As in Fig. 3, but for the thermocline depth Δh (CI is 1 m for $|h| < 6$ and 2 m for $|h| > 6$) and Ekman pumping ($W_{ek} = \nabla \times \tau/\rho f$, positive upward; CSI is $1.0 \times 10^{-6} \text{ m s}^{-1}$), which is not plotted within 2° of the equator, where it goes to infinity. Stippling denotes areas where Δh is statistically significant.

western, central, and eastern portions of the basin, respectively. The wind anomalies can excite equatorial Kelvin waves that propagate eastward, depressing the thermocline in the central and eastern Pacific, which in turn increase SSTs in these areas presumably by the eastward advection of warm water and the reduction of upwelling. These anomalies continue to grow during OND, resulting in an ENSO-like structure throughout the tropics. Once an ENSO-like structure forms, the equatorial anomalies will continue to develop through a positive Bjerknes feedback between warm equatorial SST, relaxed trade winds, and a deepening thermocline (Neelin et al. 1998). This description is consistent with

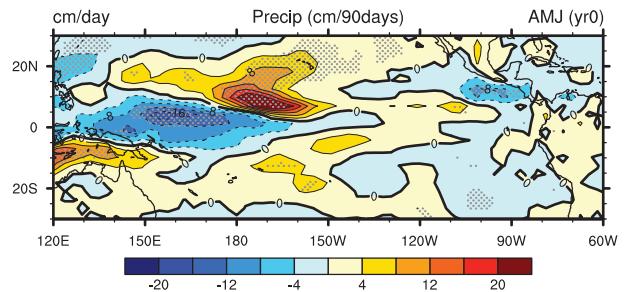

FIG. 5. The response in precipitation ΔP (CI and CSI are 4 cm per 90 days) during AMJ(0). Stippling denotes areas that are statistically significant.

the composite analysis of the MM-induced ENSO evolution in Zhang et al. (2009a).

Overall, Figs. 3–5 indicate that the evolution of the CCM-RGO-ML system both during and after the NPO forcing is applied is consistent with the SFM hypothesis: (i) the NPO forces SST anomalies to form in the eastern subtropics during winter; (ii) these SST anomalies propagate toward the equator along with westerly wind anomalies during spring; (iii) the SST and wind anomalies reach the equator in summer; and (iv) air–sea interaction amplifies the anomalous westerly wind on the equator, where they will continue to develop through a positive Bjerknes feedback between warm equatorial SSTs, relaxed trade winds, and a deepening thermocline, leading to a fully developed ENSO event in the following winter. Nearly all of these features are statistically significant at the 95% level.

One factor that complicates the interpretation of our findings is that the NPO forcing extends to 20°S ; although the imposed flux anomalies are small south of $\sim 10^\circ\text{N}$ ($|Q_{net}| < \sim 5 \text{ W m}^{-2}$; see Fig. 2), they may directly impact equatorial dynamics, thus bypassing air–sea interaction in the subtropics. We addressed this issue by performing an additional set of 10 simulations where the NPO forcing was applied north of 10°N . The results (not shown) were similar those in Figs. 3–5, where positive SST and wind anomalies formed and then amplified in the tropical Pacific during spring and summer and El Niño conditions followed in fall and winter, indicating that subtropical air–sea interactions are essential for the SFM, induced by the NPO, to influence ENSO.

Another complicating factor is that the flux forcing is only associated with the negative phase of the NPO. Thus, we performed another set of 10 simulations using the fluxes shown in Fig. 2, but with the opposite sign. The evolution of the model response to this positive phase of the NPO is similar to that presented in Figs. 3–5, but with the sign reversed (not shown). By the winter of year 1, the model response is La Niña-like with SST anomalies $< -0.6^\circ\text{C}$ over much of the equatorial Pacific (Fig. 6).

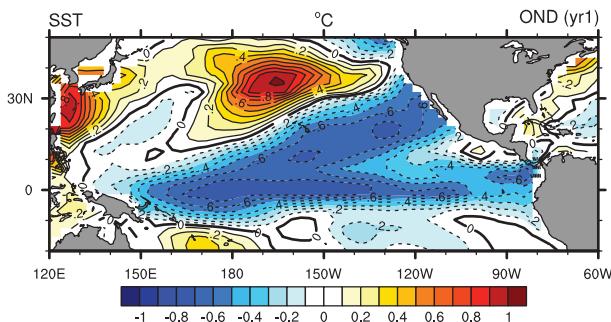

FIG. 6. The SST response (CI and CSI are 0.1°C) during OND(1) to the heat flux forcing associated with the alternate (positive) phase of the NPO.

Although there are some differences in the amplitude and pattern of the ΔSST to the two phases of the NPO (cf. forcing Fig. 6 and Fig. 3, bottom left), this may be primarily due to internal fluctuations in the climate model rather than to nonlinearities in the response to the NPO; isolating the nonlinear signal would likely require an extremely large ensemble of simulations with forcings of different amplitudes associated with both phases of the NPO.

We examine the evolution of the NPO-induced response further using Hovmöller diagrams constructed with pentad averaged model output. To highlight the evolution of the SFM, the Hovmöller path has a “j” shape that has been rotated by 90° (Fig. 7); that is, it begins at 25°N , 155°W (point 0) and extends southwestward to 12°N , 165°W (point 5); then due south to 0° (point 10); and finally due east along the equator to 85°W (point 26). The ensemble averaged Exp–Cntrl values shown for SST, Q_{lh} , and U in Fig. 7 are three-point averages including the points along and perpendicular to the transect line. In response to the imposed forcing, the ΔSST (contours in Figs. 7a,b) increases from November(0) through February(0) and remain above 0.6°C through April north of $\sim 18^{\circ}\text{N}$ (points 0–4). During February–June(0), positive (negative) wind speed (Q_{lh}) anomalies are located over the positive ΔSST , points 0–4. The stronger winds and warmer SSTs both contribute to enhanced upward latent heat flux ($\Delta Q_{\text{lh}} < 0$) through more turbulent mixing in the atmosphere (stronger winds) and an increased vertical humidity gradient (warmer SSTs), damping the underlying ΔSST . Positive ΔQ_{lh} and negative ΔU values between points 5 and 9, concurrent with the fluxes damping the NPO-forced anomalies albeit at a reduced amplitude, result in ΔSST values that decrease in magnitude as they propagate toward the equator (down and to the right in Figs. 7a,b) with $\Delta\text{SST} > 0.2^{\circ}$ arriving at position 10 during June–July(0). The negative wind speed anomalies, indicative of westerly wind anomalies, along with positive heat flux

anomalies propagate onto the equator and are located there through summer. The ΔSST subsequently amplifies and spreads eastward along the equator, reaching a maximum of $\sim 0.5^{\circ}\text{C}$ in the central–eastern Pacific (points 10–22) from November(1) to January(1), whereas the positive ΔU and negative ΔQ_{lh} remain in the central Pacific (points 10–15) through the winter of year 1.

A second propagating signal is seen in all three fields in Fig. 7: the anomalies start in the eastern equatorial Pacific in spring (points 22–25) and move rapidly westward, reaching the central Pacific (points 10–12) by summer. The SST, U , and Q_{lh} anomalies are in quadrature, with $-\Delta U$ and $+\Delta Q_{\text{lh}}$ ($+\Delta U$ and $-\Delta Q_{\text{lh}}$) located to the west (east) of the $+\Delta\text{SST}$, which is consistent with thermodynamic air–sea interaction contributing to westward propagation of the anomalies. The ΔQ_{lh} anomalies are too weak to explain the ΔSST , but strong zonal current anomalies associated with this feature (not shown) indicate that equatorial dynamics likely plays an important role in its evolution. These westward-propagating SST, Q_{lh} , and U anomalies merge with those that moved equatorward from the subtropical North Pacific (positions 5–10) from June(0) to September(0).

The evolution of Δh in Fig. 4 indicates a westward expansion of the positive thermocline depth anomalies from approximately 2° to 7°N from JFM(0) to AMJ(0) and an eastward movement of depth anomalies along the equator from JFM(0) through OND(1). In addition, ENSO is known to involve westward-propagating Rossby waves, which are centered around 5° latitude for the first baroclinic mode and southward- and eastward-propagating Kelvin waves located along the western boundary and equator, respectively. Thus, we construct a three-panel Hovmöller diagram of 5-day running mean Δh with transects centered at 5°N , along the western boundary at 132.5°E , and on the equator (Fig. 8). The transect along 5°N is reversed (east on the left) to aid in tracking anomalies that travel counterclockwise around the basin. Westward propagation of thermocline anomalies is readily apparent along 5°N in the perturbed simulations. In particular, positive Δh values that form in the central Pacific ($\sim 160^{\circ}\text{W}$) during March–April(0) reach the western boundary by summer, consistent with the group velocity of the first baroclinic Rossby wave (about 1 m s^{-1}). Upon reaching the boundary, the anomalies rapidly propagate south and then eastward along the equator, consistent with Kelvin wave dynamics. The equatorial Kelvin wave(s) appear to propagate all the way to the eastern boundary over ~ 2 months during spring and summer, but the magnitude of the anomalies are not of uniform across the equator. They may constructively interfere with the thermocline anomalies generated by local westerly wind anomalies in the vicinity of

Qflux-CNTRL 5dyrm Parallel Anom

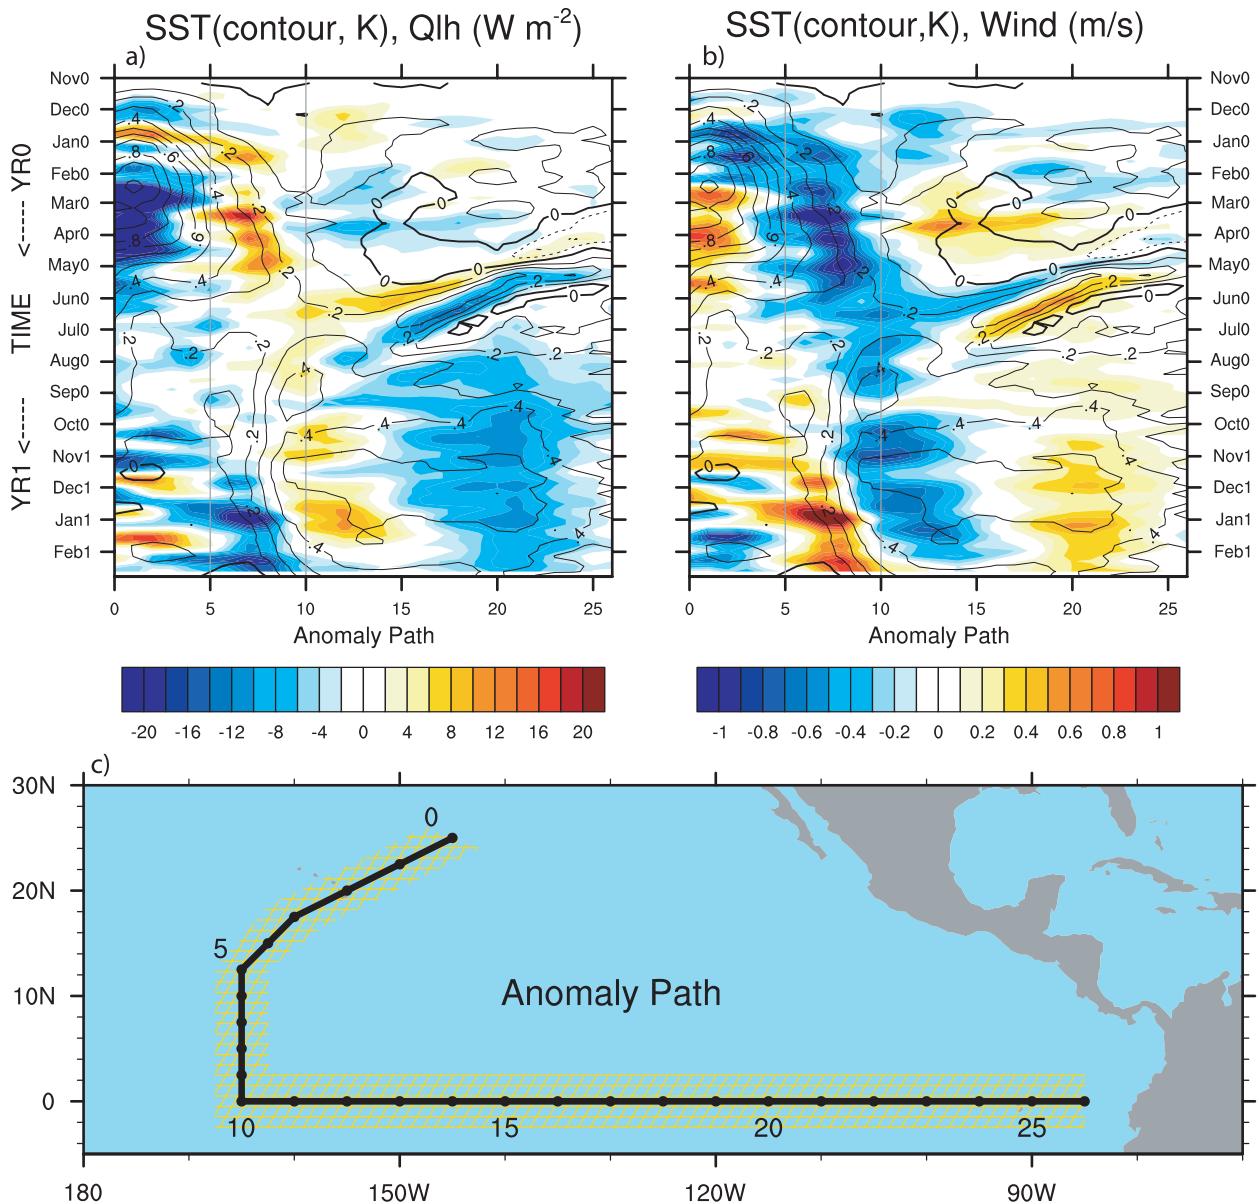

FIG. 7. Hovmöller diagrams of (a) ΔQ_{lh} (CSI is 2 W m^{-2}) and (b) ΔU (CSI is 0.1 m s^{-1}), where ΔSST (CI is 0.1°C) is shown in both. (c) The Hovmöller path consists of three sections: (i) 25°N , 155°W extending southwest to 12°N , 165°W ; (ii) south along 165°W to the equator; and (iii) east along the equator to 85°W . These correspond to points (i) 0–5, (ii) 5–10, and (iii) 10–26 along the entire transect. All values are derived from Exp–Cntrl 5-day running means averaged over three grid values, including the points on and to either side of the transect line.

$180^\circ\text{--}160^\circ\text{W}$, where the latter initially developed during March(0). In addition, Δh decreases in amplitude on the equator from approximately 140°W in June(0) to the date line in August(0) followed by an increase in amplitude slightly to the east. The latter results from a shoaling of the thermocline in advance (to the west) and a deepening behind the westward-propagating ΔSST (Fig. 7). Thus, additional processes may contribute to the SFM

in the CCM–RGO model, including oceanic Rossby waves that reflect off the western boundary and SST–wind anomalies that propagate rapidly westward along the equator.

b. ENSO characteristics

The impact of the imposed forcing on the development of ENSO is further explored in Fig. 9, which shows

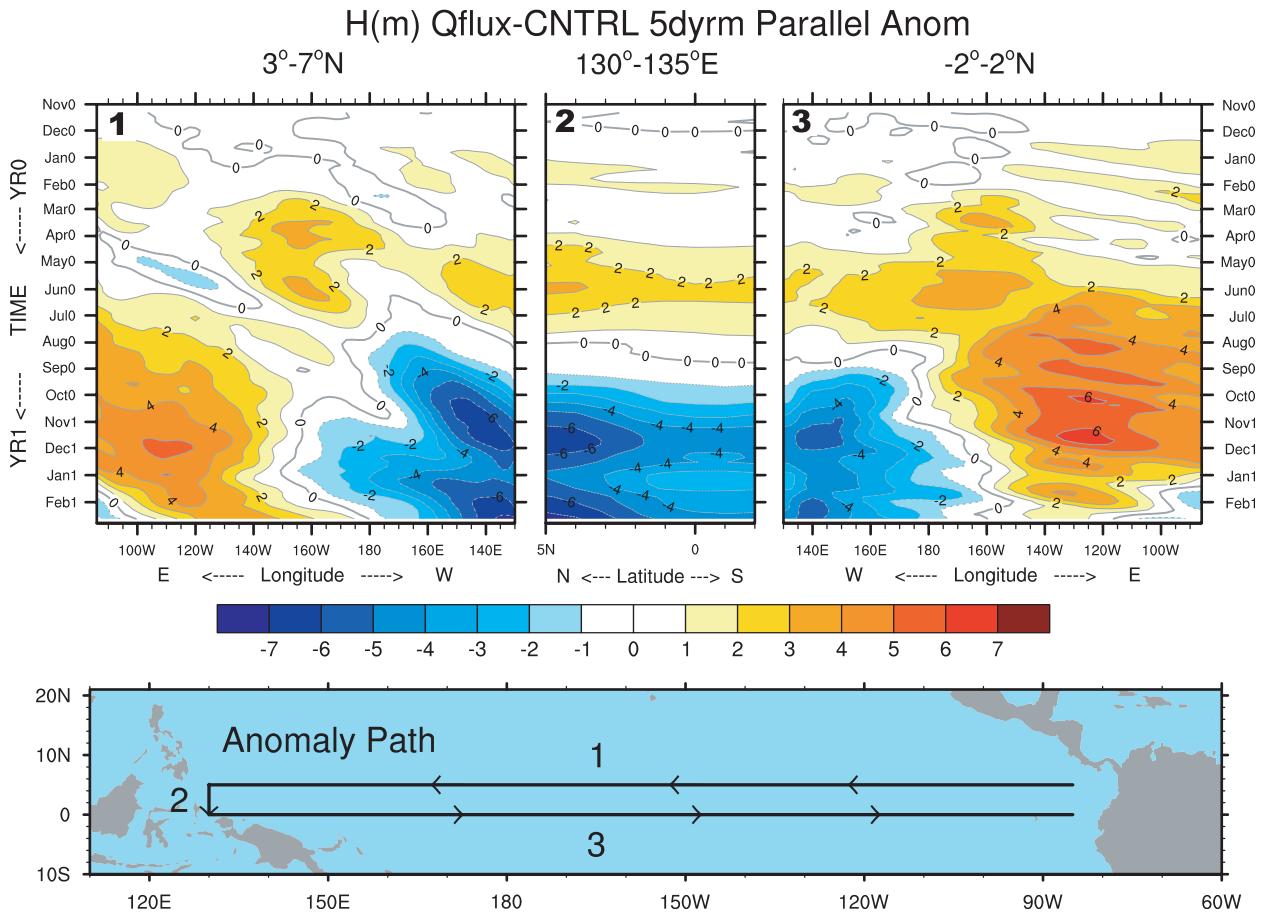

FIG. 8. (a) As in Fig. 6, but for Hovmöller diagram of (a) Δh (CI/CSI is 1 m) consisting of (b) three sections that form a counterclockwise circuit around the tropical Pacific, which extend (i) from east to west averaged over 3°–7°N; (ii) from 5°N south to the equator averaged over 130°–135°E, and (iii) from west to east averaged over to 2°N–2°S.

the difference in SST during NDJ(1) between each of the 60 Exp branch simulations and the corresponding period for the Cntrl in the Niño-3.4 region. The mean difference between the two is 0.47°C (significant at the 99% level). The SSTs warmed in the Niño-3.4 region in the subsequent winter after the forcing was applied in 43 of the 60 cases (~72%). The 17 cases that cooled are dispersed throughout the ensemble. Including the forcing added 11 more warm events, as indicated by the number of ensemble members in which the Niño-3.4 Δ SST > 0.89, 1 σ of SST averaged over NDJ in the Cntrl.

Are there additional factors that influence the extent to which the NPO-related forcing impacts the development of ENSO? We address this question via a scatterplot of Δ SST during NDJ(1) versus the SST departures relative to the long-term mean in the Cntrl (denoted by a prime) for the corresponding period (Fig. 10). Thus, the *x* axis in Fig. 10 indicates whether the control simulation develops into an ENSO event, and the *y* axis indicates the departure from the control trajectory resulting

from imposition of the NPO-related heat flux. The NPO-driven response in the 60 cases, numbered in Fig. 10 by their corresponding years in the control simulation, vary greatly from year to year of the integration; for example, the largest Δ SST values (red dots in Fig. 10) are not clustered in consecutive years. Thus, the response does not appear to be strongly influenced by decadal variability in the Cntrl integration. The ENSO response is also relatively independent of the strength of the NPO forcing in the Cntrl, because the correlation between the NPO time series in NDJFM(0) and the Niño-3.4 Δ SST in NDJ(1) is only 0.13, with no nonlinear relationship apparent from the scatterplot (not shown).

If the response to the imposed forcing was linear (independent of the conditions in the control) plus noise, then the points would appear as scatter about a horizontal line with the average Δ SST value in Fig. 10. However, a more complex response maybe anticipated; that is, the efficacy of the stochastic forcing likely depends on the state of the tropical Pacific. One possible cause

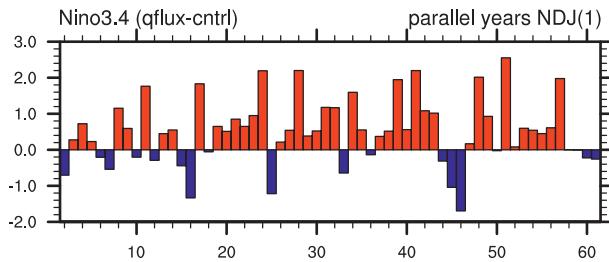

FIG. 9. Bar chart of the Exp – Cntrl (Δ) SST ($^{\circ}$ C) during NDJ(1) in the Niño-3.4 region for each of the 60 branch simulations numbered by the order of the year they occur in the control run.

of a nonlinear response is saturation; that is, the total Niño-3.4 temperature has a maximum value and thus Δ SST could be large and positive when a La Niña event is expected in the Cntrl simulation (negative SST'), positive and moderate amplitude for events that would have been neutral ENSO events, and asymptote toward zero when an El Niño event was expected from the Cntrl simulation (positive SST'). The points in Fig. 10 do display a negative slope (correlation of -0.44), indicating that the NPO forces the system toward an El Niño (Δ SST > 0) when it had negative SST' in the Cntrl simulation. However, there is not clear evidence for saturation for large SST' but rather an indication that the imposed forcing disrupted strong El Niño events in the Cntrl, because Δ SST < 0 when SST' > 0 . The true dependence of the response on the climate state, however, may require a very large ensemble to be well defined. In addition, the application of a constant forcing in the Exp simulations may result in a different mean state that could impact the overall variability and hence the mean spread in Δ SST.

An intriguing aspect of the NPO-induced responses shown in Fig. 10 are the branch simulations that developed very large Δ SSTs during NDJ(1) when the Cntrl was slightly cold or near neutral (red points). We explore the causes for these eight warm cases by compositing their associated SST' and Δ SST fields and comparing them to composites of eight cases with similar SST' values but near zero Δ SST in NDJ(1), called neutral cases (shown by blue points in Fig. 10). The composite SST' and h' fields for NDJ in years 0 and 1 for the neutral and warm cases are shown in Fig. 11 along with the Δ SST and Δh in NDJ(1), where the arrows between panels illustrates the progression of the system with and without forcing. Consistent with Fig. 10, weak La Niña conditions occur in the tropical Pacific during NDJ(1) in the Cntrl for both the neutral (Fig. 11b) and warm (Fig. 11e) cases. In the neutral composite, El Niño conditions were present in the Cntrl during NDJ(0) (Fig. 11a), and the imposition of the NPO forcing has little impact on the

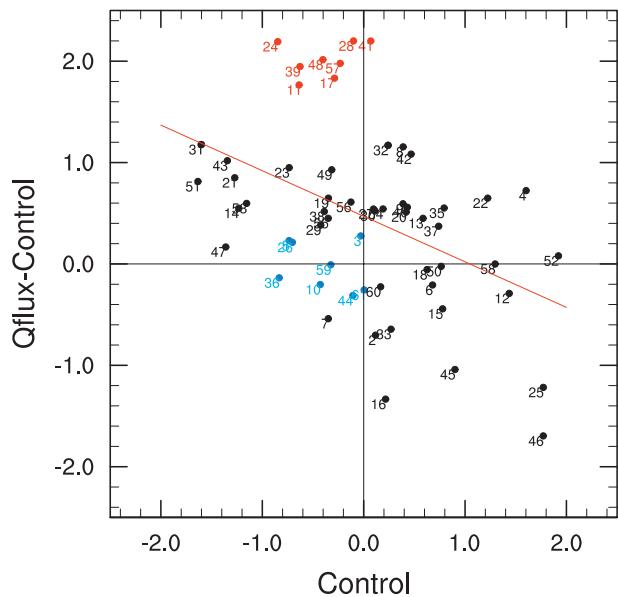

FIG. 10. Scatterplot of Δ SST versus the corresponding SST anomaly ($'$) relative to the long-term mean in the Cntrl during NDJ(1) in the Niño-3.4 region. The 60 cases are numbered by the year they occur in the control. The eight simulations with the largest or warm response are shown in red, whereas eight years with similar SST' values but near zero Δ SST (neutral cases) are shown in blue.

system, as indicated by the negligible Δ SST and Δh in the eastern equatorial Pacific during NDJ(1) (Fig. 11c). Given that El Niño events decay in less than one year and there are two or more years between events, the addition of NPO forcing appears to be ineffective in generating El Niño conditions in the subsequent winter when a warm event is currently in progress. In the absence of stochastic forcing, this version of the model maintains weak ENSO variability (i.e., the ENSO mode is in a weakly nonlinear state; Chang et al. 2007; Zhang et al. 2009b); therefore, during large El Niño events the imposition of external forcing does not appear strong enough to veer the system from its trajectory toward a La Niña. In contrast, the evolution of Cntrl simulation from the years used in the warm composite shows modest negative SST' values in the central Pacific and a deeper thermocline in the western Pacific in the winter of years 0 and 1. The addition of the NPO forcing results in a very strong Δ SST and Δh response that resembles a mature El Niño event over the entire domain by NDJ(1) (Fig. 11f). This suggests that the SFM may be an especially effective trigger for warm events when the tropical Pacific would otherwise tend toward consecutive La Niñas. The combined influence of the SFM with a deeper thermocline in the western Pacific on ENSO is also consistent with Anderson (2007), who found that anomalous low pressure in the northern subtropics is a more effective at

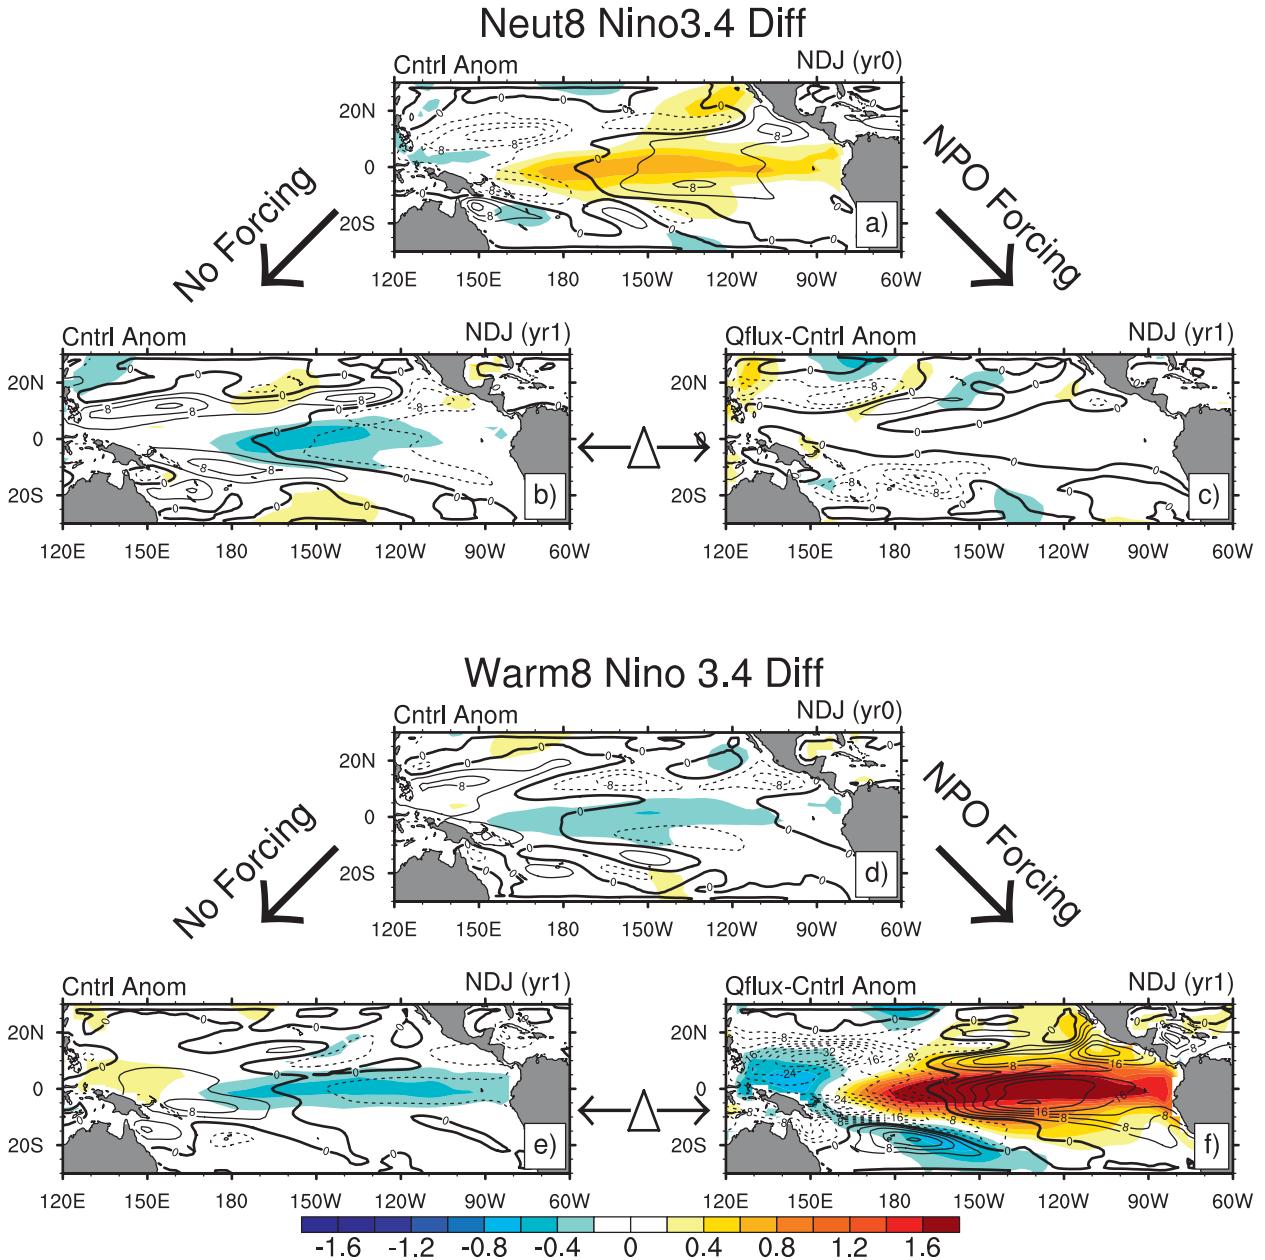

FIG. 11. (a)–(c) SST (shading) and h (contours) changes in the neutral composite. initiating an El Niño event when combined with an increase in heat content in the western equatorial Pacific a year before an event.

In addition to the initial state in the Cntrl, the evolution of anomalies in the tropical Pacific may also depend on both local and remote air–sea interactions induced by the imposed forcing, even though the latter is identical in all of the cases. As a result, the Exp–Cntrl values may differ between cases at the end of the forcing

period, which could then amplify with time as the system freely evolves over the next 12 months. We investigate this idea by showing ΔSST and Δh during March(0), near the end of the period with anomalous forcing, for the neutral and warm composites in Fig. 12. Although positive ΔSST s are found in the vicinity of Hawaii in both sets of composites, differences between the two occur in multiple locations. The positive ΔSST during March(0) in subtropical North Pacific extends farther west between

Neut8 vs Warm8 Nino3.4 Diff

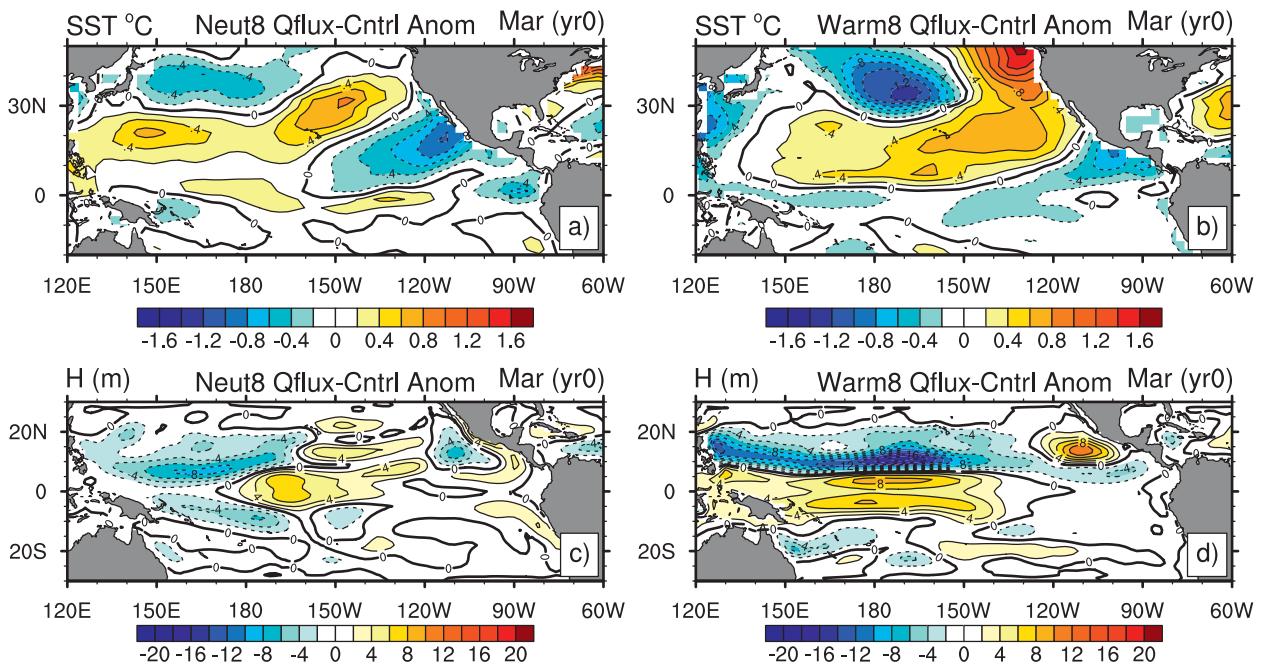

FIG. 12. The Δ SST (CI and CSI are 0.2°C) for the (a) neutral and (b) warm composite and the Δh (CI and CSI are 2 m) for the (c) neutral and (d) warm composite in March(0).

10° and 20°N in the neutral compared with the warm composite. The negative Δ SST near Central America is of larger amplitude and greater extent in the neutral cases, whereas the large negative values that occur along the entire southern coast of Asia in the warm composite are absent from the neutral composite.

The Δh during March(0) is also markedly different in the two composites (Figs. 12c,d). In the neutral case, the forcing results in a deeper thermocline on the equator in the central Pacific and a shallower thermocline off the equator in the western Pacific. In the warm composite, the thermocline is deeper off the equator, with maxima along 5°N and 5°S from 160°E to 150°W and shallower across most of the basin between 10° and 20°N . The $\Delta h > 0$ at $\sim 5^{\circ}$ latitude is indicative of downwelling gravest mode Rossby waves, which in the “delayed oscillator mechanism” (Schopf and Suarez 1988; Battisti and Hirst 1989) propagate westward to the western boundary; move equatorward along the boundary; and then move east along the equator, depressing the thermocline and creating ENSO conditions approximately 6–10 months later (consistent with Fig. 8). The anomaly structure in Fig. 12d is also consistent with the recharge/discharge ENSO paradigm (Jin 1997; Meinen and McPhadden 2000), where changes in heat storage, indicated by thermocline depth anomalies, are nearly zonally uniform at all latitudes with positive values located off the equator prior

to ENSO events. At the peak of the event, h is deep in the east and shallow in the west along the equator, which is also the structure of Δh in NDJ(1) (not shown but similar in pattern to the anomalies in Fig. 4d but with 2–3 times the amplitude).

Although it is unclear which aspects of the model’s base state at the start of the integration or the evolution of the response during the forcing period are critical to the formation of an El Niño event by the following winter, the Δ SST in the warm composite during March(0) strongly resembles the meridional mode, which has been identified as a precursor for ENSO events (Chiang and Vimont 2004; Chang et al. 2007; Zhang et al. 2009a,b). Both display SST anomalies of one sign that extend southwestward from Baja California to the equator between 150°E and 180° and anomalies of the opposite sign occur near the equator in the eastern half of the basin. Thus, NPO-related forcing may be more effective in exciting El Niño events if tropical air–sea interaction results in a strong projection on the MM during boreal spring.

4. Discussion and conclusions

The seasonal footprinting mechanism was examined using an atmospheric GCM coupled to a Cane and Zebiak type of reduced gravity ocean model in the tropics and a slab ocean model in the extratropics. The impact of

extratropical variability on the development of ENSO events is investigated through a comparison of a control simulation with 60 branch simulations that include identical external forcing. The forcing consists of the surface heat flux anomalies associated with the North Pacific Oscillation, the second leading SLP mode over the extratropical Pacific. The forcing, derived from the negative phase of the NPO (high pressure over Alaska and low pressure near Hawaii), warms the central subtropical Pacific through winter but is terminated by mid-April.

The results show that boreal wintertime midlatitude atmospheric variability associated with the NPO is capable of exciting an ENSO-like response in the tropical Pacific beginning in boreal spring/summer and amplifying through the following fall and winter. Off-equatorial anomalies reach the equator through a combination of thermodynamically coupled air–sea interactions, namely, the WES feedback and equatorial ocean dynamics. The initial off-equatorial anomaly propagates toward the equator through a relaxation of the climatological easterlies south of the dominant SST anomalies, which leads to a reduction in upward latent heat flux. These westerly anomalies reach the equator during boreal summer (Fig. 7), where they can excite downwelling equatorial Kelvin waves. The connection between off-equatorial variations and tropical ENSO-like conditions may also occur via the excitation of westward-propagating equatorial Rossby waves during the boreal spring immediately following the wintertime imposed forcing. These Rossby waves reflect off of the western boundary as equatorward-propagating Kelvin waves, depressing the thermocline in the eastern Pacific during the following summer (Fig. 8). The Rossby wave mechanism appears to be especially prominent in the cases with the largest response (Fig. 12) and resembles the precursor to El Niño events in the delayed oscillator and recharge/discharge paradigms for ENSO. The depressed thermocline is associated with warmer SST and likely initiates a Bjerknes-type feedback that allows El Niño conditions to continue to develop.

In addition to the off-equatorial anomalies that take several months to reach the equator, there are also SST, wind, and thermocline depth anomalies that form on the equator in the eastern Pacific ($\sim 90^\circ\text{W}$) in spring and propagate rapidly westward, reaching the central Pacific ($\sim 160^\circ\text{W}$) by summer (Fig. 7). Although the role of this feature in the SFM is unclear, it resembles the “mobile mode” described by Mantua and Battisti (1995) and the “Pacific Ocean basin (POB) mode” identified by Jin et al. (2003) and Kang et al. (2004) and has been found in observations, the Cane and Zebiak model, and GCMs. In addition, these studies have found that the equatorial SST anomalies are primarily driven by anomalous zonal

currents, which is consistent with the large zonal currents associated with the westward-propagating anomalies excited by the NPO forcing in our experiments. Analyses of shallow water models (Mantua and Battisti 1995; Kang et al. 2004) indicate that the time scale of the POB mode, which is independent of the ~ 4 -yr ENSO mode, is approximately 9–12 months and is set by the time it takes the gravest free Rossby wave and coastal/equatorial Kelvin waves to propagate around the basin. Air–sea coupling destabilizes the POB mode, allowing it to grow rapidly for certain base states, and influences SST anomalies in the ENSO region.

Although the imposition of the NPO-related forcing caused warming in the ENSO region in $\sim 70\%$ of the 60 branch simulations, the impact of the forcing on individual events depends on the state of the tropical ocean–atmosphere system. For years where the control simulation was poised to develop into a neutral or negative ENSO event, the addition of the NPO heat fluxes tended to cause anomalous warming relative to the control simulation in the tropical Pacific in the following fall/winter. On the other hand, if the control trajectory were heading toward a warm ENSO event, the imposition of NPO-related heat fluxes tends to reduce the amplitude of that event. This is consistent with results in Zhang et al. (2009b, their Fig. 9), who found that $\sim 70\%$ of ENSO events were initiated by the MM in a long control integration. A possible explanation is that the MM-induced warming in the north tropical Pacific can work in concert with an existing cold anomaly in the equatorial Pacific to enhance the meridional SST gradient, causing a stronger thermodynamic feedback that acts to intensify or at least persist the MM. In contrast, a preexisting warming condition near the equator works against the MM development because it tends to weaken the meridional SST gradient.

The spatial structure of NPO-related heat flux anomalies in the tropical Pacific bears a strong resemblance to the meridional mode. Although this suggests that the MM is simply due to the SFM, other studies have found that the MM exists independent of external forcing (Xie 1997, 1999; Okajima et al. 2003; Chang et al. 2007; Kossin and Vimont 2007; Zhang et al. 2009a,b). The MM dynamics include an equatorward and westward propagation of SST anomalies (Liu and Xie 1994; VAF; Zhang et al. 2009a), which is consistent with the evolution of SST anomalies in the present analysis. As such, the SFM may be a means of exciting the tropical Pacific MM, the dynamics of which ultimately lead to tropical Pacific variations that amplify via the Bjerknes feedback. In this way, the SFM, MM, and ENSO fit together in a dynamic framework where the SFM plays a dominant role in forcing the MM, whereas the MM acts as a conduit through which the extratropical atmosphere influences ENSO.

Changes in other NPO-related variables could also impact the tropical Pacific. For example, changes in zonal wind stress associated with the NPO could directly impact equatorial ocean dynamics, instead of as part of the response to the subtropical SSTs generated by the surface heat fluxes. In addition, the SFM is clearly not the only means of exciting tropical Pacific variability. As shown in Fig. 10, there is considerable ENSO variability that is not explained by the imposed NPO-related heat fluxes. In particular, the importance of WWBs in the initiation of ENSO events has been highlighted by various authors (e.g., McPhaden et al. 1988; Vecchi and Harrison 2000; McPhaden 2004; Seiki and Takayabu 2007). The spatial structure of SST anomalies that are associated with periods of excessive westerly wind burst activity bears a strong resemblance to the NPO-related SST anomalies (Vecchi and Harrison 2000). An examination of high-pass filtered daily output from the CCM-RGO model, however, did not show an increase in the number and/or intensity of WWBs in the NPO-forced simulations relative to the control. Nevertheless, the relationship between WWBs and the SFM should be more fully explored in coupled GCMs and observations.
